Abstract. In the classical hidden Markov chain (HMC) model we have a hidden chain X, which is a Markov one and an observed chain Y. HMC are widely used; however, in some situations they have to be replaced by the more general "hidden semi-Markov chains" (HSMC) which are particular "triplet Markov chains" (TMC) $T=(X,U,Y)$, where the auxiliary chain U models the semi-Markovianity of X. Otherwise, non stationary classical HMC can also be modeled by a triplet Markov stationary chain with, as a consequence, the possibility of parameters' estimation. The aim of this paper is to use simultaneously both properties. We consider a non stationary HSMC and model it as a TMC $T=(X,U^1,U^2,Y)$, where U^1 models the semi-Markovianity and U^2 models the non stationarity. The TMC T being itself stationary, all parameters can be estimated by the general "Iterative Conditional Estimation" (ICE) method, which leads to unsupervised segmentation. We present some experiments showing the interest of the new model and related processing in image segmentation area.

Key Words: Non-stationary hidden semi-Markov chain, unsupervised segmentation, iterative conditional estimation, triplet Markov chain.

PACS: 02.50.Ga

Notations: In this article all the processes and random variables will be defined on the abstract probability space $(E,\mathcal{E},\Pr)$.
The processes will be written in upper case letters and their realizations in lower case letters. The marginals will be indexed by the corresponding indexes.
Except ambiguities $p(t|s)$ will denote $\Pr(T=t|S=s)$ with the corresponding letters. If T is continuous, this last one will be a probability density function (pdf).

INTRODUCTION

In the classical hidden Markov chain (HMC) model there is a hidden random chain X, which is a Markov one and an observed chain Y. HMCs are efficient and widely used in numerous problems; however, in some situations they have to be replaced by the more general "hidden semi-Markov chains" (HSMC) [3, 5, 7, 10, 11]. Otherwise, it has been recently showed that HSMC are particular "triplet Markov chains" (TMC [8]) $T=(X,U,Y)$, where an auxiliary chain U models the fact that X is semi-Markov [9]. Furthermore, it has been also showed that a non stationary classical hidden Markov chain can also be seen as a triplet Markov stationary

chain with, as a consequence, the possibility of parameters' estimation [6]. The aim of this paper is to use simultaneously both properties. We firstly consider a TMC $T^1 = (X, U^1, Y)$, which is equivalent to a hidden semi-Markov chain. Then we consider that T^1 is not stationary, which is modeled by a second auxiliary random chain U^2. Finally, we consider $T = (X, U^1, U^2, Y)$ as a TMC $T = (X, U, Y)$ with the auxiliary process $U = (U^1, U^2)$. Therefore we have a stationary TMC $T = (X, U, Y)$ which models a non stationary HSMC (NSHSMC). We propose to use such a $T = (X, U, Y)$ in unsupervised hidden discrete signal segmentation. The parameters' estimation is performed by an original variant of the general "Iterative Conditional Estimation" (ICE) method [1, 2, 4] and the Bayesian segmentation is performed by the cassical Maximum Posterior Mode (MPM) method. The interest of the new modeling and related processing are validated by some experiments.

MODELING HIDDEN NON STATIONARY SEMI-MARKOV CHAINS WITH TRIPLET MARKOV CHAINS

Let us consider $Z = (X, Y)$ with $X = (X_1, ..., X_n)$ and $Y = (Y_1, ..., Y_n)$ two random chains where each X_i takes its values in a finite set of classes $\Omega = \{\omega_1, ..., \omega_K\}$, and each Y_i takes its values in $\mathbb{R}$. Classically, $Z = (X, Y)$ is a hidden semi-Markov chain when X is a semi-Markov chain and when the distribution of Y conditional on X is given by $p(y|x) = p(y_1|x_1)...p(y_n|x_n)$. Otherwise, a possible way to define semi-Markov distribution of X is to say that this is a marginal distribution of a particular Markov chain. More precisely, one considers a random chain $U^1 = (U_1^1, ..., U_n^1)$, where each U_i^1 takes its values in the set of positive integers $\mathbb{N}^* = \{1, 2, ...\}$, such that the couple (X, U) is a Markov chain defined by $p(x_1, u_1^1)$ and transitions $p(x_{i+1}, u_{i+1}^1 | x_i, u_i^1)$. For each $i = 1, ..., n$ and $x_i \in \Omega$, one considers a probability distribution $p(.|x_i)$ on $\mathbb{N}^*$ such that for $j \in \mathbb{N}^*$, $p(j|x_i)$ is the probability that $(X_{i-1}, X_i, ..., X_{i+j-1}, X_{i+j}) = (x_{i-1}, x_i, x_i, ..., x_i, x_{i+j})$ and $x_{i-1} \neq x_i$ and $x_{i+j} \neq x_i$. This models the fact that the distribution of the "sojourn time" of the chain X in a given state can be of any form, while it is necessarily of geometrical form in Markov chains. More precisely, a semi-Markov distribution of X is the marginal distribution of a Markov chain (X, U^1) whose distribution is given by $p(x_1, u_1^1)$ and the following transitions $p(x_{i+1}, u_{i+1}^1 | x_i, u_i^1) = p(x_{i+1}|x_i, u_i^1) p(u_{i+1}^1 | x_{i+1}, x_i, u_{i+1}^1)$:

$$p(x_{i+1}|x_i, u_i^1) = \begin{cases} \delta_{x_i}(x_{i+1}) \text{ if } u_i^1 > 1 \\ p(x_{i+1}|x_i) \text{ if } u_i^1 = 1 \end{cases} \text{ with } p(x_{i+1} = x_i | x_i) = 0 \quad (1)$$

$$p(u_{i+1}^1 | x_{i+1}, x_i, u_i^1) = \begin{cases} \delta_{u_i^1 - 1}(u_{i+1}^1) \text{ if } u_i^1 > 1 \\ p(u_{i+1}^1 | x_{i+1}) \text{ if } u_i^1 = 1 \end{cases} \quad (2)$$

where $\delta_x(.)$ is the Dirac measure on x. Let us notice that the variable $U_i^1 = u_i^1$ designates the remaining sojourn time in the state x_i.

Returning to the observation Y, we can say that the distribution of a hidden semi-Markov chain $Z = (X, Y)$ is the marginal distribution of a particular triplet Markov chain $T^1 = (X, U^1, Y)$. Let us put temporarily $V = (X, U^1)$. As V is a Markov chain,

$T^1 = (V,Y)$ is a hidden Markov chain and we can model its possible non stationarity by introducing an auxiliary random chain $U^2 = (U_1^2, ..., U_n^2)$, each U_i^2 taking its values in a finite set $\Lambda^2 = \{1, ..., M\}$. This leads to a TMC $T = (V,U^2,Y)$, which also is a TMC $T = (X,U,Y)$, with the auxiliary process $U = (U^1,U^2)$. Its distribution is given by $p(x,u^1,u^2)$ and $p(y|x,u^1,u^2) = p(y|x)$. Otherwise, the distribution $p(x,u^1,u^2)$ of (X,U^1,U^2) is given by $p(x_1,u_1^1,u_1^2)$ and the transitions $p(x_{i+1},u_{i+1}^1,u_{i+1}^2|x_i,u_i^1,u_i^2)$ that we can write as $p(x_{i+1},u_{i+1}^1,u_{i+1}^2|x_i,u_i^1,u_i^2) = p(u_{i+1}^2|x_i,u_i^1,u_i^2)p(x_{i+1}|u_{i+1}^2,x_i,u_i^1,u_i^2)p(u_{i+1}^1|x_{i+1},u_{i+1}^2,x_i,u_i^1,u_i^2)$.
The particular transitions in this product, that define the new model we propose and that generalize formulas (1)-(2) above, are the following:

$$p(u_{i+1}^2|x_i,u_i^1,u_i^2) = \begin{cases} \delta_{u_i^2}(u_{i+1}^2) \text{ if } u_i^1 > 1 \\ p(u_{i+1}^2|u_i^2) \text{ if } u_i^1 = 1 \end{cases} \tag{3}$$

$$p(x_{i+1}|u_{i+1}^2,x_i,u_i^1,u_i^2) = \begin{cases} \delta_{x_i}(x_{i+1}) \text{ if } u_i^1 > 1 \\ p(x_{i+1}|u_{i+1}^2,x_i) \text{ if } u_i^1 = 1 \end{cases} \tag{4}$$

$$p(u_{i+1}^1|x_{i+1},u_{i+1}^2,x_i,u_i^1,u_i^2) = \begin{cases} \delta_{u_i^1-1}(u_{i+1}^1) \text{ if } u_i^1 > 1 \\ p(u_{i+1}^1|u_{i+1}^2,x_{i+1}) \text{ if } u_i^1 = 1 \end{cases} \tag{5}$$

$p(x,u^1,u^2)$ being defined with (3)-(5), we end the definition of $T = (X,U,Y)$ by considering $p(y|x,u^1,u^2) = p(y_1|x_1)...p(y_n|x_n)$.
Finally, putting $W = (X,U^1,U^2)$, we can say that $T = (W,Y)$ is a classical hidden Markov chain in which W is discrete and Y is continuous. However, let us remark that the model is a particular one; in fact, we have $p(y_i|x_i,u_i^1,u_i^2) = p(y_i|x_i)$, which means that the noise 's distribution does not depend on u_i^1 and u_i^2. Of course, one can imagine that this noise distribution does depend on u_i^1, u_i^2 or even both of them, and the possibility of taking this into account in the model provides its possible further extensions.
Finally, having a classical hidden Markov chain allows us to compute $p(x_i,u_i^1,u_i^2|y)$ by using the classical "forward-backward" algorithm, then $p(x_i|y) = \sum_{u_i^1,u_i^2} p(x_i,u_i^1,u_i^2|y)$ and the MPM solution is given by $\hat{x_i} = \arg\max p(x_i|y)$.
Concerning the parameters' estimation we use the "Iterative Conditional Estimation" (ICE) described below.

PARAMETERS' ESTIMATION AND BAYESIAN SEGMENTATION

In experiments below we will use the following particular case of the model (3)-(5). We will consider that U_i^1 takes its values in a finite set $\Lambda^1 = \{1, ..., P\}$ and that $p(x_{i+1} = x_i|u_{i+1}^2,x_i,u_i^1 = 1)$ is not necessarily null. This condition means that for $U_i^1 = 1$ the value $U_{i+1}^1 = u_{i+1}^1$ is not the exact sojourn duration in x_{i+1} but the minimal duration. This define a particular distribution of sojourn time on $\mathbb{N}^*$ which allows us to perform direct calculations without resorting on Monte Carlo

methods.
Let us remark that a given distribution of W does not necessarily define an unique distribution of X; however this problem does not arise in our experiments and we will not deal with any more in this paper.
From now, we will define by W the hidden process, which will be either $W=(X,U^1)$ or $W=(X,U^1,U^2)$. From the definition of the model seen above, W is a Markov chain thus (W,Y) is a classical hidden Markov chain (HMC). We will assume that $p(y_i|x_i=\omega_j)$ does not depend on i and is gaussian distributed with mean m_j and variance σ_j^2. Moreover $p(w_i,w_{i+1})$ does not depend on i.
Finally, as each (X_i,U_i^1,U_i^2) takes its values in a finite set $\{\omega_1,...,\omega_K\}\times\{1,...,M\}\times\{1,...,P\}$, the whole model is defined by $(K\times M\times P)^2$ real parameters giving the distribution $p(w_1,w_2)$, K means and K variances. We propose to estimate all these parameters from the observation $Y=y$ by a method derived from the general "Iterative Conditional Estimation" (ICE).
According to its general principle, one can apply ICE to estimate a vector of parameters θ from Y once:

1. There exists an estimator $\hat{\theta}(W,Y)$ of θ from complete data (W,Y).
2. For every θ one can sample W according to $p(w|y,\theta)$.

The iterative ICE method runs as following:

1. Consider an initial value[1] θ^0 ;
2. Put $\theta_r^{q+1}=\mathbb{E}[\hat{\theta}_r(W,Y)|Y=y,\theta^q]$ for the component θ_r of θ for which this expectation is computable ;
3. For other components, sample m realizations $w^{q,1}$,...,$w^{q,m}$ of W according to $p(w|y,\theta^q)$ and put $\theta_r^{q+1}=\dfrac{\hat{\theta_r}(w^{q,1},y)+...+\hat{\theta}_r(w^{q,m},y)}{m}$.

Let us consider the case $W=(X,U^1)$, as the case $W=(X,U^1,U^2)$ can be dealt with in a similar way. There are $(K\times P)^2$ parameters $p_{ij}=\Pr(W_1=i,W_2=j)$ (therefore W_1 and W_2 are both in $\{\omega_1,...,\omega_K\}\times\{1,...,P\}$), K means m_1,...,m_K and K variances σ_1^2,...,σ_K^2. Denoting by I the indicator function, the classical estimator from complete data that we use is (we assume n odd):

$$\hat{p_{ij}}(w,y)=\frac{2}{n}\sum_{m=1}^{\frac{n}{2}}I(w_{2m-1}=i,w_{2m}=j) \tag{6}$$

$$\hat{m}_l(w,y)=\frac{\sum_{m=1}^{n}y_mI(x_m=\omega_l)}{\sum_{m=1}^{n}I(x_m=\omega_l)} \tag{7}$$

[1] This value can be set by using K-means classification.

$$\hat{\sigma_l^2}(w,y) = \frac{\sum_{m=1}^{n}(y_m - \hat{m}_l(w,y))^2 I(x_m = \omega_l)}{\sum_{m=1}^{n} I(x_m = \omega_l)} \tag{8}$$

Recalling that the expectation of an indicator function is the probability of the corresponding set and applying the conditional expectation $\mathbb{E}(\hat{p_{ij}}(W,y)|Y=y,\theta^p)$ to (6) gives:

$$p_{ij}^{q+1}(y) = \frac{2}{n}\sum_{m=1}^{\frac{n}{2}} p(w_{2m-1}=i, w_{2m}=j|y,\theta^q) \tag{9}$$

while its application to (7) and (8) is not computable and we resort on sampling. This sampling is workable, as $p(w|y,\theta^q)$ is a Markov chain with calculable transitions $p(w_{k+1}|w_k,y,\theta^q)$ (see below). Then we simulate one sample w^q (we take $m=1$ in 3.) and (7), (8) are applied to (w^q,y) instead of (w,y).
Finally, in order to perform unsupervised segmentation using ICE, we have to calculate the following three distributions: $p(w_{k+1}|w_k,y,\theta^q)$, $p(w_k,w_{k+1}|y,\theta^q)$ needed in ICE, and $p(w_k|y,\theta^q)$ needed in Bayesian MPM segmentation method. These distributions are classically computed from "forward" $\alpha_k(w_k) = p(w_k|y_1,...,y_k)$ and "backward" $\beta_k = p(y_{k+1},...,y_n|w_k,y_k)$ coefficients, which are computed by the folowing forward (10) and backward (11) recursions:

$$\begin{gathered}\alpha_1(w_1) = p(w_1|y_1) \text{ and} \\ \alpha_{k+1}(w_{k+1}) = \sum_{w_k}\alpha_k(w_k)p(w_{k+1},y_{k+1}|w_k,y_k),\ \forall k \in \{2,...,n-1\};\end{gathered} \tag{10}$$

$$\begin{gathered}\beta_n(w_n) = 1 \text{ and} \\ \beta_k(w_k) = \sum_{w_{k+1}}\beta_{k+1}(w_{k+1})p(w_{k+1},y_{k+1}|w_k,y_k),\ \forall k \in \{n-1,...,1\};\end{gathered} \tag{11}$$

Then we have:

$$p(w_k,w_{k+1},y|\theta^q) = \alpha_k(w_k)\beta_{k+1}(w_{k+1})p(w_{k+1},y_{k+1}|w_k,y_k); \tag{12}$$

this last equation gives $p(w_{k+1}|w_k,y,\theta^q)$, $p(w_k,w_{k+1}|y,\theta^q)$ and $p(w_k|y,\theta^q)$.

EXPERIMENTS

We present below two series of experiments.
In the first one, we simulate a particular hidden semi-Markov non stationary chain, where X takes its values in $\Omega = \{\omega_1,\omega_2\}$, U^1 takes its values in $\Lambda^1 = \{1,...,5\}$ and U^2 takes its values in $\Lambda^2 = \{0,1\}$ which means that there are two different stationarities. The distributions $p(y_i|x_i)$ are normal with a common standard

deviation equal to 1 and the means are equal to 1 and 1.5 according to the value of x_i respectively. We have:

$$p(u_{i+1}^2|u_i^2, u_i^1 = 1) = \begin{pmatrix} 0.999 & 0.001 \\ 0.001 & 0.999 \end{pmatrix} ;$$

$$(p(x_{i+1}|u_{i+1}^2 = 0 \text{ or } 1, u_i^1 = 1, x_i))_{x_i, x_{i+1}} = \begin{pmatrix} 0.99 & 0.01 \\ 0.01 & 0.99 \end{pmatrix} \text{ and } \begin{pmatrix} 0.7 & 0.3 \\ 0.3 & 0.7 \end{pmatrix} ;$$

$$p(u_{i+1}^1|u_{i+1}^2, u_i^1 = 1, x_{i+1}) = \frac{1}{5}, \forall u_{i+1}^1, u_{i+1}^2, x_{i+1} ;$$

Moreover the initial distribution $\pi(w_1) = p(w_1)$ is calculed by resolving $\pi Q = \pi$ where Q is the transition 's kernel of the Markov chain $W = (X, U^1, U^2)$. One can show this last one is $\pi(w_1) = \frac{1}{K \times P \times M}$ for all w_1.
The observation $Y = y$ is then segmented by three unsupervised methods. The first method is based on the very classical HMC model, the second one is based on a stationary HSMC, and the last one is based on the proposed TMC, equivalent to a NSHSMC. Of course, as the data follow the new model, the very Bayesian theory requires that its use gives better results than the two others. However, the experiment is of interest because the three segmentations are performed in unsupervised manner, and in a rather strongly noisy context. Then the theorical superiority of NSHSMC based method is no longer true, and the use of a simpler model like HSMC or even HMC, which contains less parameters to be estimated, could possibly produce better results than the use of NSHSMC. Let us notice that a possible application is image segmentation, where the use of monodimensional chains is possible by associating the mono-dimensional process with th bi-dimensional process set of pixels by using the Hilbert-Peano curve [1, 2, 4, 6]. The images $X = x$, $U^2 = u^2$ and $Y = y$ so obtained are presented in Figure 1. The results show that the theoretic hierarchy is saved in the unsupervised segmentation: NSHSMC works better than stationary HSMC and stationary HSMC works better than stationary HMC. Otherwise, in spite of the very high level of the noise (see $Y = y$ in Figure 1), the estimation with ICE gives quite satisfying results when using NSHSMC (see Table 1).
In the second experiment, we consider a two classes-image $X = x$ and its noisy version $Y = y$ (see Figure 2, obtained by the use of Hilbert-Peano curve). As in the experiment above, $Y = y$ is segmented by the same three unsupervised methods. Of course, the data follow none of the three models and thus the objective here is to study how each model works in such a case. As we can see in Table 2 and Figure 2, the same hierarchy is respected. Therefore we see that the NSHSMC based unsupervised method is better than the HSMC method, and the latter method is better than the HMC based one.
Concerning ICE, we have initialized θ by using K-means.

CONCLUSION

In this paper, we have proposed a new model of a hidden non stationary semi-Markov chains. Extending some first suggestions presented in [9], the general idea was to use a triplet Markov chain $T = (X, U, Y)$ with $U = (U^1, U^2)$, where U^1 models the semi-markovianity and U^2 models the non-stationarity. As $T = (X, U, Y)$ is itself stationary, it is possible to estimate its parameters using the general "Iterative Conditional Estimation" (ICE) method, which leads to unsupervised Bayesian segmentation methods. We proposed two series of experiments which show that, on the one hand, the hidden semi-Markov chains based unsupervised segmentation method works better than the classical hidden Markov chains based unsupervised segmentation method and, on the other hand, the new model based unsupervised segmentation method works better than the hidden semi-Markov chains model.
The classical hidden Markov chains are applied in various areas like Biosciences, Climatology, Communications, Ecology, Econometrics and Finance, Image or Signal processing. Therefore, the model we propose in this paper is likely to be useful and improve different processings in the same applications.
